Exercises to prevent lower limb injuries in youth sports: cluster randomised controlled trial
Odd-Egil Olsen, Grethe Myklebust, Lars Engebretsen, Ingar Holme, Roald Bahr

Abstract

Objective To investigate the effect of a structured warm-up programme designed to reduce the incidence of knee and ankle injuries in youth sports.

Design Cluster randomised controlled trial with clubs as the unit of randomisation.

Setting 120 team handball clubs from central and eastern Norway (61 clubs in the intervention group, 59 in the control group) followed for one league season (eight months).

Participants 1837 players aged 15-17 years; 958 players (808 female and 150 male) in the intervention group; 879 players (778 female and 101 male) in the control group.

Intervention A structured warm-up programme to improve running, cutting, and landing technique as well as neuromuscular control, balance, and strength.

Main outcome measure The rate of acute injuries to the knee or ankle.

Results During the season, 129 acute knee or ankle injuries occurred; 81 injuries in the control group (0.9 (SE 0.09) injuries per 1000 player hours; 0.3 (SE 0.17) in training vs 5.3 (SE 0.06) during matches) and 48 injuries in the intervention group (0.5 (SE 0.11) injuries per 1000 player hours; 0.2 (SE 0.18) in training vs 2.5 (SE 0.06) during matches). Fewer injured players were in the intervention group than in the control group (46 (4.8%) in the control group vs 76 (8.0%); relative risk intervention group vs control group 0.53, 95% confidence interval 0.35 to 0.81).

Conclusion A structured programme of warm-up exercises can prevent knee and ankle injuries in young people playing sports. Preventive training should therefore be introduced as an integral part of youth sports programmes.

Introduction

Regular physical activity reduces the risk of premature mortality in general and of coronary heart disease, hypertension, colon cancer, obesity, and diabetes mellitus in particular. However, participation in sports also entails a risk of injury for all athletes, from the elite to the recreational level. Studies from Scandinavia document that sports injuries constitute 10-19% of all acute injuries seen in emergency departments, and the most common types are knee and ankle injuries. Serious knee injuries, such as injuries to the anterior cruciate ligament, are a growing cause of concern. The highest incidence is seen in adolescents playing pivoting sports such as football, basketball, and team handball. In these sports, women are three to five times more likely to contract a serious knee injury than men.

Injuries to the anterior cruciate ligament may require surgery, always entail a long rehabilitation period, and drastically increase the risk of long term sequelae. Although treatment methods have advanced notably, there is no evidence to show that repair of a ruptured anterior cruciate ligament or isolated cartilage lesions prevents early development of osteoarthritis. Effective methods for preventing injuries therefore need to be developed.

Some studies report promising results, indicating that it may be possible to reduce the incidence of knee and ankle injuries among adults and adolescents. However, these studies are small and mainly non-randomised, with important methodological limitations. Prospective randomised intervention studies are therefore needed, especially among children and adolescents, to assess the efficacy of interventions aiming to reduce injuries.

We conducted a randomised controlled trial to investigate the effect of a structured programme of warm-up exercises used to prevent acute injuries of the lower limb in young people playing sports. To minimise overlap within clubs, we used a cluster design.

Methods

One hundred and twenty three clubs agreed to participate in the study, and we block randomised these, with four clubs in each block to an intervention or control group. To reduce potential confounding, we matched the clubs by region, playing level, and sex and number of players. The statistician (IH) who conducted the randomisation was not involved in the intervention. Box 1 gives details of the procedure used to recruit clubs.

We informed clubs allocated to the intervention group that they would receive a programme of warm-up exercises used to prevent injuries. We asked the clubs in the control group to do their training as usual during the season and informed them that they would receive the same programme as the intervention group at the start of the subsequent season.

Box 1: Recruiting clubs to the study

- All 145 clubs in the 16 year and 17 year divisions from central and eastern Norway, organised by the Norwegian Handball Federation, received an invitation to participate in the study during one eight month season (September 2002 to April 2003)
- The clubs practised one to five times per week and played between 20 and 50 matches during the season, depending on their ability and ambition
- The clubs were recruited from June to August 2002 through the website of the Norwegian Handball Federation, and a letter with information about the purpose and the design of the study went to the coaches, who also informed the players
Papers

Intervention

The warm-up programme was developed by medical staff from the Oslo Sports Trauma Research Center and coaching staff from the Norwegian Handball Federation, and its feasibility had been tested in four clubs during the previous season. The programme included four different sets of exercises, each of increasing difficulty.

At the start of the league season (September), the clubs in the intervention group received one visit from an instructor from the handball federation. In addition, instructors followed up the clubs with a visit midway through the season (January). The instructors had been familiarised with the programme during a two hour seminar, in which they received theoretical and practical training on how to conduct the programme. The clubs received an exercise book, five wobble boards (disc diameter 38 cm; Norpro, Notodden, Norway, 2000) and five balance mats (40×50 cm², 7 cm thick; Alusuisse Airex, Sins, Switzerland, 2000).

The coaches were asked to use the programme at the beginning of every training session for 15 consecutive sessions and then once a week during the remainder of the season. The main focus of the exercises was to improve awareness and control of knees and ankles during standing, running, cutting, jumping, and landing. The programme consisted of exercises with the ball, including the use of the wobble board and balance mat (box 2, fig 1, and fig 2), for warm up, technique, balance, and strength.

The players were encouraged to be focused and conscious of the quality of their movements, with emphasis given to core stability and position of the hip and knee in relation to the foot (the “knee over toe” position). They were also asked to watch each other closely and give each other feedback during the training. They were instructed to spend 4-5 minutes on each exercise group for a total duration of 15-20 minutes.

Data on injury and exposure were reported by the physiotherapists using a web based database in which all the data were coded anonymously. At the end of the season, the recorded data were confirmed, or if necessary corrected, by the coaches.

Box 2: Programme of warm-up exercises used to prevent injuries

**Warm-up exercises**

(30 seconds and one repetition each)
- Jogging end to end
- Jogging 30 m (3 minutes and 5×10 repetitions each)
- Forward running with sidesteps
- Forward running with knee lifts and heel kicks
- Sideways running with crossovers (“caricara”)
- Sideways running with arms lifted (“parade”)
- Forward running with trunk rotations
- Forward running with intermittent stops
- Speed run

**Technique**

(One exercise during each training session; 4 minutes and 5×30 seconds each)
- Planting and cutting movements
- Jump shot landings

**Balance**

(On a balance mat or wobble board, one exercise during each training session; 4 minutes and 2×90 seconds each)
- Passing the ball (two leg stance)
- Squats (one or two leg stance)
- Passing the ball (one leg stance)
- Bouncing the ball with eyes closed
- Pushing each other off balance

**Strength and power**

(2 minutes and 3×10 repetitions each)
- One quadriceps exercise:
  - Squats to 80° of knee flexion
  - Bounding strides (“Springlauf”)
- Forward jumps
- Jump shot—two legged landing
- “Nordic hamstring lowering” (2 minutes and 3×10 repetitions each)

**Outcomes measures**

We defined the primary outcome as an acute injury to the knee or ankle. A secondary outcome was defined as any injury to the lower limbs. We also included secondary analyses of injuries overall (including all injuries) and injuries to the upper limb. We included all injuries reported after an intervention club had completed the first session of the training aiming to prevent injuries (and from the same date in the control clubs randomised in the same block), to compare the number of injured players and incidence of injury between the intervention group and the control group.

The number of injured players was based on data from individual players and the incidence of injuries on summary data of injuries and exposures for the whole group. Data on players who dropped out during the study period were included for the entire period of their participation.

Ten research physiotherapists who were blinded to group allocation recorded injuries in both groups, using definitions (box 3) and a standardised injury questionnaire described in our earlier study (Olsen OE, Myklebust G, Engebretsen L, Bahr R. Injury pattern in youth team handball: a comparison of two prospective registration methods. Submitted for publication to *Scand J Med Sci Sports*).

The physiotherapists were in contact with the coaches at least every month to record injured players and exposure data. They interviewed injured players, either in person or by telephone, and in most cases within four weeks (range one day to four months). They were responsible for roughly the same number of clubs from each of the groups (11 to 13 clubs each).

The coaches of the clubs receiving the intervention recorded compliance on a designated form as the number of injury prevention sessions, the duration of each session in minutes, and the average attendance of the players (in per cent). At the end of the season we also obtained information on prevention training conducted by the control clubs, including the types and volume of exercises used.

**Sample size**

In youth team handball, the incidence of acute injuries to the knee and ankle is estimated to be 12 per 100 players per league season. From a pilot study conducted to determine the incidence of injury during the previous season (submitted for publication), we estimated that the cluster effects for club randomisation gave an inflation factor of 2.0 based on a cluster size of 15 and an intraclass correlation coefficient of 0.07. We then calculated that to achieve 90% power with $\alpha = 5\%$ to detect a relative risk reduction of 50%, we would need 915 players in each group. Therefore, when we initiated the trial, we were hoping to include 60 clubs in each group (a total of 120 clubs; with an average of 15 players in each club).

**Statistical methods**

We used Stata, version 8.0 (Stata Corporation, Lakeway Drive, Texas, 2003), for the statistical analysis. We undertook all statistical analyses according to a prespecified plan. We used the...
relative risk of the number of injured players according to the intention to treat principle to compare the risk of an injury in the intervention and control groups. Cox regression was our analysis tool for the primary outcome as well as the secondary outcomes, and we used the robust calculation method of the variance-covariance matrix,\textsuperscript{16} taking into account the cluster randomisation. We tested rate ratios with Wald's test. We used one way analysis of variance to estimate the intraclass correlation coefficient to obtain estimates of the inflation factor for comparison with planned sample size. We used the inverse of the difference between percentages of injured players in the two groups to calculate the number needed to treat to save one injury. We calculated exposures to training and matches and incidence of injury as described in our earlier study.

Compliance and incidence of injury are presented as means with standard errors. Relative risk and rate ratio are presented with 95% confidence intervals. We regarded two tailed P values \( \leq 0.05 \) as significant.

Results

Figure 3 shows the flow of clubs and players through the trial. Players in the two groups were similar in sex distribution, age, and dropout rates (table 1). All but eight (13%) of the clubs in the intervention group used the programme of warm-up exercises used to prevent injuries during the study period. Also, 13 (22%) of the clubs in the control group used specific exercises intended to prevent injuries (including training on the balance mat and wobble board) as a part of their training.
Injury prevention programme:

- **Clubs**: 61 in the first part and 13 in the second part (January to April).
- **Training sessions (SE, range)**: 27 (12, 1-55) in the first part and 26 (7, 14-35) in the second part.
- **Average time spent per session in minutes (SE)**: 18 (6) in the first part and 18 (9) in the second part.
- **Average attendance per session in %**: 73% in the first part and 78% in second part.

### Box 3: Operational definitions used in the registration of injury

**Reportable injury**: An injury occurred during a scheduled match or training session, causing the player to require medical treatment or miss part of or the next match or training session.

**Player**: A player was entered into the study if she or he was aged 15-17 years (born between 1 January 1985 and 31 December 1987), was registered on the club roster by the coach, and did not have a major injury at the start of the study.

**Return to participation**: The player was defined as injured until he or she was able to participate fully in club activities (match and training sessions).

**Type of injury**: Acute—injury with a sudden onset associated with a known trauma.

**Severity**: Slight—0 days of absence and able to participate fully in the next match or training session. Moderate—absence from match or training for 8-21 days. Major—absence from match or training for > 21 days.

**Exposure**: Match exposure—hours of matches. Training exposure—hours of training. In nearly all cases, players sustaining moderate or major injuries were examined by a doctor. If there was any doubt about the diagnosis the player was referred to a sport doctor or a sports medicine centre for follow up, which often included imaging studies or arthroscopic examination. In case of a slight or minor injury, the player was often examined only by a physical therapist or coach or not at all. None of the injured players was examined or treated by any of the authors, and we had no influence on the time it took a player to return to club activities.

### Injury characteristics

During the eight month season, 298 injuries were included in the study contracted a total of 298 injuries. Of these, 241 (81%) were acute injuries and 57 (19%) were overuse injuries. Table 2 shows the location of the most common body part injured, the type of acute and overuse injuries, and the age of the injured players.

**Effect of prevention**

Significantly fewer injured players were in the intervention group than in the control group for injuries overall, lower limb injuries, acute knee or ankle injuries, and acute knee and upper limb injuries, whereas a 37% reduction in acute ankle injuries did not reach significance (table 3). The degrees of clustering at the club level (intraclass correlation coefficient) were estimated to be 0.043 to 0.071. The number needed to treat to prevent one injury varied from 11 to 59 players.

The exposure in hours for the intervention group was 93 812 (11 210 hours spent in matches, 82 602 hours in training) and in the control group 87 483 hours (10 783 hours in matches, 76 700 hours in training).

* Cox model calculated according to method of Lin and Wei,17 which takes cluster randomisation into account.

76 700 hours in training). Table 4 shows the severity of injury for different types of injury. Injuries overall, acute injuries, and acute knee or ankle injuries differed significantly, whereas reductions in 7-53% for slight injuries and 18-59% in minor injuries did not reach significance. The overall difference in the incidence of match and training injuries was also significant, whereas acute injuries and acute knee or ankle injuries differed only for matches (table 5). The 13 control clubs using training exercises to prevent injuries had a significantly lower incidence of injuries than the clubs in the control group doing no prevention training (rate ratio: all injuries 0.48, 95% confidence interval 0.31 to 0.76; P = 0.001; lower limb injuries 0.35, 0.19 to 0.63; P = 0.001; acute injuries 0.47, 0.29 to 0.76; P = 0.002; acute knee or ankle injuries 0.22, 0.09 to 0.55; P = 0.001). No category of injury differed by sex.

Discussion

The rate of injuries in adolescent athletes using a structured warm-up programme as a part of their training improved clinically and statistically, especially the rate of severe injuries to the knee and ankle. The reduction in the relative risk is highly significant and has been adjusted for the cluster sampling, which takes into account the analytical limitations of a cluster randomised study. As far as we are aware, our study is the first randomised controlled trial among adolescents with a sufficient sample size to show that acute knee or ankle injuries can be reduced by 50% and severe injuries even more.

Data validation

The trial took place in the divisions comprising 16 year and 17 year olds from large geographical regions of Norway and.

¶Same type and location of injury.
Ported by data from Ebstrup and Boysen-Møller et al. Other sports, including both men’s and women’s team handball, indicated that a programme of balance and cutting exercises focusing on the anterior cruciate ligament among adult women’s team handball players indicate a pattern of knee and ankle injuries, and the injury mechanism is similar to what is observed in other pivoting sports, such as volleyball. However, these sports have a high incidence and are less demanding than handball or volleyball. Therefore, it seems reasonable to develop warm-up exercises that are effective in preventing injuries to the knee and ankle. Based on the results of the current study, we recommend that warm-up exercises should be part of the training programme. The exercises used in the programme were developed on the basis of previous intervention studies in team handball. The programme also included a strength exercise, the "Nordic hamstring lower" exercise, which has been shown to be effective in improving eccentric hamstring muscle strength among adult male soccer players. Since the hamstrings can act as agonists to the anterior cruciate ligament during stop and jump tasks, it is possible that stronger hamstrings muscles can prevent injuries to the ligament, but this theory has never been tested. Further studies are needed to determine what the key component(s) of the programme are in reducing risk of injury. In this way it may be possible to develop even more specific programmes that require less time and effort and may be suitable for "weekend recreational" athletes too.

Compliance

On comparison with a previous study that investigated the prevention of injuries to the anterior cruciate ligament at the senior level, we found a considerably higher compliance (87%) among the youth clubs. In view of the media attention focusing on the problem of injuries to the anterior cruciate ligament in women’s team handball, we were surprised to find that only 29% of the clubs participating in a similar non-randomised study of adult players fulfilled the compliance criteria. However, this study, and our intervention study, may have motivated some of the youth clubs to include exercises to prevent injuries as a regular part of their training programme, as evidenced by the crossover observed in 29% of the control clubs. In support of the study findings, these clubs had a significantly lower incidence of injuries than the other control clubs. Also, not all clubs continued to use the programme of warm-up exercises used to prevent injuries after the initial intensive introduction period. However, we included all the clubs in an intention to treat analysis, which means that the effect of the programme may be even higher than we have reported.

Structured programme of warm-up exercises to prevent injuries

The exercises used in the programme were developed on the basis of previous intervention studies in team handball and other sports, and had been feasibility tested and modified to be suitable for team handball. The focus on alignment of the hip, knee, and ankle—especially the knee over toe position—was supported by data from Ebstrup and Boysen-Møller and Olsen et al. Their video analyses of the mechanisms for injuries of the anterior cruciate ligament in team handball indicate that players could benefit from not allowing the knee to sag medially during plant and cut movements or when suddenly changing speed. The programme therefore focused on the proper technique for planting and cutting movements, aiming at a narrower stance as well as a knee over toe position. Recent data from a study investigating the prevention of injuries to the anterior cruciate ligament among adult women’s team handball players indicate that a programme of balance and cutting exercises focusing on knee control not only prevents injuries but also improves dynamic balance and that this effect is maintained for at least 12 months. One randomised study from senior men’s elite soccer also showed a substantial decrease in the rate of injuries to the anterior cruciate ligament as a result of a static balance training programme using a balance board.

The prevention programme that we tested is multifaceted and considers many aspects that could be related to the risk for injury (agility, balance, strength, awareness of vulnerable positions of the knee and ankle, playing technique), and it is not possible to determine exactly which part of the programme may be effective in preventing injuries to the knee and ankle. Based on data from volleyball, our programme also focused on landing on both legs after jumps rather than just one leg, and with an emphasis on increased hip and knee flexion to attenuate the landing. The programme also included a strength exercise, the “Nordic hamstring lower” exercise, which has been shown to be effective in improving eccentric hamstring muscle strength among adult male soccer players. Since the hamstrings can act as agonists to the anterior cruciate ligament during stop and jump tasks, it is possible that stronger hamstrings muscles can prevent injuries to the ligament, but this theory has never been tested. Further studies are needed to determine what the key component(s) of the programme are in reducing risk of injury, and it seems warranted to examine the physiological effects of each programme component, as well as the effect on injury risk. In this way it may be possible to develop even more specific programmes that require less time and effort and may be suitable for “weekend recreational” athletes too.

Although injuries to the anterior cruciate ligament are a particular concern, especially in women’s pivoting sports, it was not possible to plan this investigation on young players to determine the effect of the intervention programme on rates of injury to the anterior cruciate ligament alone. Our power calculations indicated that a study looking at ruptures of the anterior cruciate ligament would have needed 12,000 players in each group to detect a 50% reduction in such injuries. Even so, we found an 80% reduction in ruptures of knee ligaments (anterior cruciate ligament, posterior cruciate ligament, and medial collateral ligament) in the intervention group, which reached significance.

Generalisability

We used youth team handball (age 15-17) as a case of youth sports in our trial. Since the intervention was implemented for both sexes and at different levels, the result indicates that the youth elite as well as the intermediate and recreational players would benefit from using the warm-up programme to prevent injuries. We do not know if the results can be generalised to other age groups or to other youth sports such as football, basketball, or volleyball. However, these sports have a high incidence and similar pattern of knee and ankle injuries, and the injury mechanisms are also comparable (most injuries resulting from pivoting and landing movements). Therefore it seems reasonable to

Table 5 Number of acute injuries, acute knee or ankle injuries, and incidence of injuries during matches and training. Incidence is reported as the number of injuries per 1000 player hours, with standard errors

What is already known on this topic

Sports injuries constitute 10-19% of all acute injuries treated in emergency departments, with injuries to the knee and ankle the most common types.

The risk of serious knee injuries, such as injuries to the anterior cruciate ligament, is high among adolescents playing pivoting sports such as football, basketball, or team handball.

It may be possible to reduce the incidence of knee and ankle injuries among young people, but studies showing this have been small and mainly non-randomised, with significant methodological limitations.

What this study adds

A structured warm-up programme designed to improve awareness and knee and ankle control during landing and pivoting movements prevents knee and ankle injuries among youth athletes.

The incidence of knee and ankle injuries can be reduced by at least 50%.

Preventive training should be routine in training programmes for adolescents in pivoting sports.

assume that the prevention programme used in the present study also could be modified to be used in other similar sports. Moreover, if the goal is to develop movement patterns that are more resistant to injury, it may be easier to work with even younger players who have not yet established their motion patterns. Therefore, we suggest that programmes focusing on technique (cutting and landing movements) and balance training (on wobble boards, mats or similar equipments) are implemented in players as young as 10-12 years.

Conclusion

A structured warm-up programme designed to improve awareness and control of knees and ankles during landing and pivoting movements reduces injuries to the lower limb in youth team handball. Preventive training should therefore be introduced as a natural part of youth sports training programmes in similar pivoting sports.

Acknowledgements: We thank the physiotherapists, instructors, coaches, and players who participated in this study and Norwegian Handball Federation staff and officials for practical support.

Contributors: OEO, GM, LE, IH, and RB contributed to study conception and design. OEO coordinated the study and managed all aspects of the trial, including developing, testing, and finalising the intervention, and data collection. IH conducted and initialised the blinded data analyses, which were planned and checked with OEO. OEO and RB wrote the first draft of the paper, and all authors contributed to the final manuscript. OEO is guarantor.

Funding: The Oslo Sports Trauma Research Center has been established at the Norwegian University of Sport and Physical Education through generous grants from the Royal Norwegian Ministry of Culture, the Norwegian Olympic Committee and Confederation of Sport, Norsk Tipping, and Pfizer. In addition, this study was supported by grants from the Norwegian Sports Medicine Foundation, the Norwegian Handball Federation, and If insurance.

Ethical approval: Ethical approval was not required by the regional committee for medical research ethics.
